tive athletes; younger people are often involved. For this reason there is growing concern about long-term adverse effects of these substances.

We recently observed a case of Hodgkin's lymphoma occurring in a 31-year-old, non-smoking, white male patient. From the ages of 10 to 27 years he had been a semi-professional cyclist, riding competitively with a team. He reported habitual, long-lasting consumption of testosterone and other anabolic steroids, caffeine, and amphetamines. Moreover, he reported at least four subsequent administrations of high (supra-therapeutical) doses of growth hormone.

Four years after withdrawal from competitive activity, the patient presented with right inguinal lymphoadenopathy, in the absence of any symptom. Histological examination revealed lymphocyte-predominant Hodgkin's lymphoma. Total-body axial tomography and bone marrow biopsy excluded other localizations (IA stage). Serology for Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, herpesvirus, and toxoplasma was negative. The patient received three courses of adriamycin, bleomycin, vinblastine, and dacarbazine obtaining complete remission; he will also receive local radiotherapy.

Growth hormone is mitogenic for both the rat T-cell lymphoma line Nb2 and human lymphoid IM9 cells; it enhances the proliferation of human leukemic blasts [1] and increases the incidence of virus-induced B-cell lymphoma [2]. Recent reviews indicate that leukemia and related malignancies are frequently observed in GH-deficient children after GH therapy [3,4]. In our case, there was no evidence of additional risk factors for lymphoma, except for the doping. The latency period was comparable to those found in the literature for leukemia in GH-treated patients.

The use of doping in sports is probably more a moral issue than a medical one. However, the coexistence of vested interest for athletes and team managers in the use of non-legal pharmaceuticals may enlarge the field of action of criminality in sports. The suspected relationship between GH use and hematological malignancies represents a further, strong reason to discourage this practice.

Physiological Neutrophilia Is Associated With Elevated Serum Level of Macrophage Colony-Stimulating Factor (M-CSF)

To the Editor: Cincotta et al. [1] reported that physiological neutrophilia of pregnancy is not associated with a rise in plasma granulocyte colony-stimulating factor (G-CSF). We agree with this observation. Recently our colleagues reported that serum levels of macrophage colony-stimulating factor (M-CSF) are correlated with the presence of neutrophilia during pregnancy [2,3]. M-CSF plays an important role in trophoblast development and hormonal regulation of pregnancy. In early and late pregnancy, serum M-CSF levels are elevated along with the white blood cell count [4], and soon after delivery M-CSF levels return to normal.

The report of Cincotta et al. [1] about normal G-CSF levels during pregnancy is quite important. When we encounter pregnant patients who may have infections, white blood cell count is not necessarily a useful parameter for diagnosis. C-reactive protein or other inflammatory parameters should be helpful, but serum levels of G-CSF and M-CSF should also be taken into consideration to determine the clinical situation of the pregnant woman.

Kung Fu Phlebitis: An Unusual Presentation of Mondor's Disease

To the Editor: Mondor's disease, or superficial thrombophlebitis of the chest wall, is a relatively uncommon condition that has been described primarily in young and middle-aged women [1]. We report an unusual presentation of Mondor's disease in a man.

A 37-year-old man who was generally in good health presented to our outpatient clinic with a complaint of sharp, intermittent, right anterior chest wall pain that had begun 4 weeks previously. The pain was precipitated by abduction and extension of the right shoulder, and improved within minutes of repositioning the arm.

Physical examination revealed palpable cords originating near the right nipple and radiating inferiorly along the course of the thoracoepigastric vein and laterally along the course of the lateral thoracic vein. There was mild tenderness to palpation but no erythema or edema. Laboratory testing showed normal values for prothrombin time, activated partial thromboplastin time, fibrinogen, thrombin time, plasminogen, antithrombin III, protein C, protein S, dilute Russell viper venom time, and anticardiolipin antibodies. A polymerase chain reaction for factor V Leiden [2] was negative. A
